Frontal Sinus & Nasal Septum Patterns & Pneumatisation of Sphenoid Sinus: An Obscure Path for Personal Identification: A Retrospective Cone Beam Computed Tomography Study

Kalai Selvi Ravishankar[1], Saraswathi Gopal K[2], Mahesh Kumar P[3]

Abstract

Background: Identification of a body is the cornerstone of forensic investigation. If primary methods of identification are impossible (absence of comparative DNA samples, fingerprints, and teeth records), it can be performed using radiographic techniques, whenever antemortem images are available. Visual comparison of antemortem and postmortem images, such as frontal sinuses radiographics and CBCTs can allow identification. The uniqueness and reliability of frontal sinus and nasal septum patterns is used for human identification in forensic science. personal identification can also be done by assessment of pneumatisation of sphenoidal sinus.

Aim & Objectives: This study aims to evaluate the use of frontal sinus and nasal septum patterns and the pneumatisation of sphenoidal sinus for personal identification. To correlate all the parameters to find which is more accurate for identifying a person.

Materials & Method: Study Design: A Retrospective Study. *Study Population:* A study of 90 CBCT images, (45 males and 45 females) acquired from the archives that were generated using Planmeca Promax 3D MID Proface CBCT machine and assessed with Planmeca Romexis Software. *Sample size:* Sample of 90 CBCT images obtained from the archives. CBCT images of patients between 18 - 69 years of age.

Result: Pearson's Chi-Square test between gender for frontal sinus were $2=12.659$, $p=0.005<0.01$ which shows highly statistical significance between frontal sinus and gender, for nasal septum were $2=0.722$, $p=0.949>0.05$ which shows no statistical significance between nasal septum and gender, for sphenoid sinus were $2=9.574$, $p=0.008<0.01$ which shows highly statistical significance between sphenoid sinus and gender. But his study had individual variations in frontal sinus, nasal septum and sphenoid sinus for every person.

Conclusion: Imaging of the human body, especially the head and neck region, has been useful in forensic dentistry for proving medicolegal cases and in human identifications during mass disasters.

Hence, this study determines the reliability and accuracy of frontal sinus, sphenoidal sinus and nasal septum pattern as a tool for personal identification.

Keywords: Frontal sinus; Nasal septum; Sphenoid sinus; Personal identification; CBCT.

INTRODUCTION

The study of anthropometry is of fundamental importance in identification of a person and plays a vital role in medico legal investigation of a dead person. Use of features unique to each human being helps in personal identification and is widely accepted in forensics. On comparing the ante-mortem reports recorded during life time and post-mortem records, a forensic odontologist can identify the age at time of death, race and even sex[1] by study of the skull's osteological features. Personal identification can be done using various body parts, the skull, the pelvis, the long bones, the foramen magnum and the paranasal sinuses.[2]

In any natural disaster, criminal case investigation or when the body is burnt or destroyed the body remains degraded and other biological tools such as DNA analysis, fingerprint etc., fail to assess the identification of the body, forensic radiology plays an important role in personal identification as well as gender determination.[3] Identification of a body is the cornerstone of forensic investigation. If primary methods of identification[4] are impossible (absence of comparative DNA samples, fingerprints, and teeth records,[5,6] it can be performed using radiographic techniques, whenever antemortem images are available. Visual comparison of antemortem and postmortem images, such as CTs, Cone beam computed tomographies (CBCT)[7] and frontal sinuses radiographs,[8] can allow identification, if concordance of specific anatomical findings is established. If antemortem radiologic images are missing, the sex and/or the age of the corpse can be assessed using X-ray imaging of skull or postcranial elements.[9-13]

Structures in human skull such as frontal sinus, nasal septum, vascular groove patterns, sellaturcica etc., can act as useful indicators because of their uniqueness in every individual. Frontal sinus is a cavity which is lobulated. It is bilaterally situated in between the external and internal cortical surface of the frontal bone. It may vary person to person or even in monozygotic twins. The frontal sinuses are not even visible at the time of birth.[14,15] They gradually develop at the age of two years and the development completes at the age of 20 years.

The nasal septum pattern is also useful and unique tool. In each individual many types of patterns present such as Straight (S'), Left deviated (L') or Right deviated (R'), Sigmoid type (Si), Reverse sigmoid type (RSi) and Others (O) (epsilon and reverse epsilon type; rare types).[16]

Severely damaged bodies can be difficult to identify, and various factors can delay the identification.[17,18] In violent traumatic contexts, teeth and frontal sinuses can be missing, or separated into small pieces from the rest of the body, which limits their contribution to identification. Sphenoid sinuses, on the other hand, are better protected from traumatic degradation. They appear in the third year of life, contrary to frontal sinuses, which are not aerated before the age of 6 years.[19,20] As they are deeply positioned in the center of the cranial base[21] they are well protected from degradation resulting from external causes. Their pneumatization, well documented as extremely variable in degrees and directions[22-25], could contribute to the radiologic identification of a dead person.[26]

CBCT is today the reference imaging modality to study various pathologies and sinuses and it is frequently and increasingly prescribed in various countries. Unlike conventional radiography, CBCT allows an excellent visualization of the anatomical features of the frontal sinus, nasal septum and sphenoid sinuses. Sphenoid sinuses are therefore well protected, anatomically variable, and perfectly examinable on CBCT s. Their possible contribution to identification was reported, but to our knowledge, the accuracy of their forensic use has not yet been assessed. The aim of this study was to assess the frontal sinus and nasal septum patterns and the pneumatisation of sphenoid sinus in personal identification.

AIM & OBJECTIVES

- This study aims to evaluate the frontal sinus and nasal patterns and pneumatisation of sphenoidal sinus for personal identification.
- To identify an individual based on combined frontal sinus and nasal septum patterns.
- To identify an individual based on the sphenoidal sinus pneumatisation.
- To correlate all the parameters to find which is more accurate for identifying a person.

MATERIALS AND METHOD

Institutional Ethical Committee of Meenakshi Ammal Dental College & Hospital, Maduravoyal, Chennai 600095, India, in its review onlinc meeting held on 28.09.2021 at 9.00 a.m., reviewed and

discussed the study proposal with protocol number MADC/IC/III/70/2021 Entitled Significance of Frontal sinus and Nasal septum patterns and Pneumatisation of Sphenoidal sinus in personal identification: A Retrospective cone beam computed tomography study.

Full skull CBCT images of the patients reported to the institution for various dental problems taken in the time period between 2014 – 2021 were acquired from the dental archives. The scans were generated using the Planmeca Promax 3D MID Proface CBCT machine obtained at 90Kvp, 10mA and with large FOV 13x15 cm.

Study Design: A Retrospective Study.

Study Population: A study of 90 CBCT images, (45 males and 45 females) acquired from the archives that were generated using Planmeca Promax 3D MID Proface CBCT machine and assessed with Planmeca Romexis

Sample size: Sample of 90 CBCT images obtained from the archives. CBCT images of patients between 20-65 years of age.

Inclusion Criteria

- ➤ CBCT images having good resolution and image clarity.
- ➤ Patients in the age group of above 18 years of both the genders were included in the study.

Exclusion Criteria

- ➤ CBCT of patients younger than 18 are excluded.
- ➤ CBCT images with artifacts.
- ➤ Patients with maxillofacial, frontal bone and sphenoidal bone fractures and treated for the same.
- ➤ Patients diagnosed with tumors, or any pathology involving the sphenoid sinus, frontal and the nasal bone.

METHODOLOGY

## *Parameters to be Assessed*

1. *Frontal Sinus*

Frontal sinus in axial section. The different classification of frontal sinus was observed. The different types include: **Symmetry, Asymmetry,** **Unilateral aplasia, Bilateral aplasia**.

2. *Nasal Septum*

Nasal septum in coronal slice. The different patterns of nasal septum was observed. The various patterns include: Straight, Left deviation, Right deviation, Sigmoid, Reverse sigmoid.
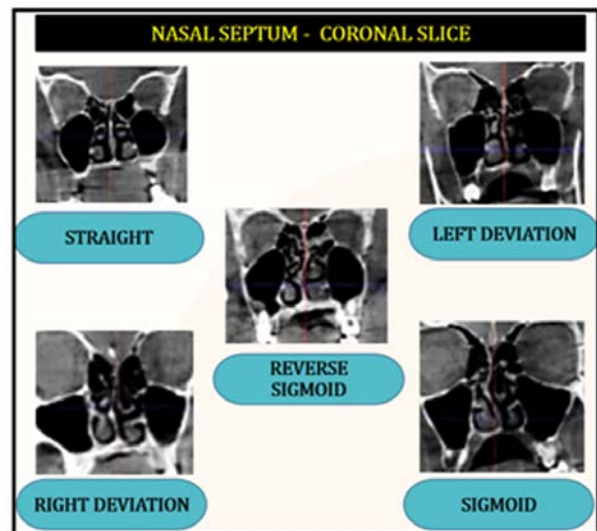

3. *Sphenoid sinus*

Sphenoid sinus was observed for its pneumatisation in sagittal and coronal section. In sagittal slices, the position of the posterior wall of the sphenoid sinuses was evaluated in relation with the anterior and posterior walls of the sellaturcica. Sinuses can be classed according to the following types: (Hammer and Radberg).

Conchal, pre-sellar, sellar, post-sellar

conchal (type I: complete missing or minimal sphenoid sinus)

pre-sellar (type II: posterior wall of sphenoid sinus is in front of the anterior wall of the sella turcica),

sellar (type III: posterior wall of sphenoid sinus is between anterior and posterior wall of sella turcica)

post-sellar (type IV: posterior wall of sphenoid sinus is behind the posterior wall of sella turcica).

In coronal slice, coronal slice through sphenoid sinus with penumatisation of pterygoid and clinoid process was observed.[31]

a: **Absence of pneumatization of the pterygoid processes.** The thick arrow indicates the right vidian canal, the long arrow shows the left foramen rotondum

b: **Pneumatization of the right and the left ptreygoid processes**, and of the right anterior clinoid process. The long thick arrow indicates the pneumatized right anterior clinoid process.

C: Both **anterior clinoid and pterygoid processes are pneumatized**. The lon thick arrow indicates the pneumatized right anterior clinoid process.

RESULTS

The collected data from the study were analysed with IBM SPSS Statistics for Windows, Version 23.0. (Armonk, NY: IBM Corp). To describe about the data descriptive statistics frequency analysis, percentage analysis were used for categorical variables and the mean & S.D were used for continuous variables. To find the significant difference between the bivariate samples in Independent groups the Unpaired sample t-test was used. To find the significance in categorical data Chi-Square test was used. In all the above statistical tools the probability value .05 is considered as significant level. In this study the frontal sinus, nasal septum and sphenoid sinus had individual variations for every person which aids us in identifying a person in a crucial hour of forensic investigation.

The Gender distribution were Female is 50.0%, Male is 50.0%. The Frontal Sinus distribution were Ia is 60.0%, Ib is 21.1%, Ic is 5.6%, Id is 13.3%. The Frontal Sinus between Gender by Pearson's Chi-Square test were $2=12.659$, $p=0.005<0.01$ which shows highly statistical significance between Frontal Sinus and Gender. The Nasal Septum distribution were IIa is 42.2%, IIb is 15.6%, IIc is 20.0%, IId is 13.3%, IIe is 8.9%. The Nasal Septum between Gender by Pearson's Chi-Square test were $2=0.722$, $p=0.949>0.05$ which shows no statistical significance between Nasal Septum and Gender. The Sphenoid Sinus distributions (In sagittal slices) were Type I is 3.3%, Type II is 26.7%, Type III is 25.6%, Type IV is 44.4%. The Sphenoid Sinus between Gender by Pearson's Chi-Square test were $2=2.991$, $p=0.393>0.05$ which shows no statistical significance between Sphenoid Sinus and Gender. The Sphenoid Sinus distribution (In axial slices)

DISCUSSION

Personal identification is defined as establishing the identity of an individual. The need for personal identification arises in natural mass disasters like earth quakes, tsunamis, landslides, floods etc., and in man-made disasters such as terrorist attacks, bomb blasts, mass murders, and in cases when the body is highly decomposed or dismembered to deliberately conceal the identity of the individual.[27] Identification using structures in the skull remains the most widely used method for personal identification. Moreover, examination of the skull becomes the only tool for identification in burnt bodies and when the skull is the only found remain. The complexity of the skull anatomy allows for analysis of many structures like nasal cavity, paranasal sinuses, sellaturcica, zygomatic processes and mandible. In the present study, CBCT was utilized for skull imaging. The methodology applied for frontal sinus, nasal septum and sphenoid sinus examination was simple, easy and reproducible.

The results of the present study the Frontal Sinus

distribution were Symmetry is 60.0%, Asymmetry is 21.1%, Unilateral aplasia is 5.6%, Bilateral aplasia is 13.3%. Nasal Septum distribution were Straight is 42.2%, Right deviation is 15.6%, Left deviation is 20.0%, Sigmoid is 13.3%, Reverse sigmoid is 8.9%. Sphenoid Sinus distribution were conchal is 3.3%, presellar is 26.7%, sellar is 25.6%, post sellar is 44.4%. Sphenoid Sinus distribution were Absence of pneumatization of the pterygoid processes is 67.8%, Pneumatization of the right and the left ptreygoid processes, and of the right anterior clinoid process is 18.9% and Both anterior clinoid and pterygoid processes are pneumatized is 13.3%. Characteristic individual variations have been noted in all the parameters which can be a useful tool for personal identification.

Taniguchi M, et al. 2003[28] suggested use of frontal sinus and nasal septum in personal identification and reported 204 different types of classification with high efficacy in identification with 95% probability. 43% symmetry in Japanese population, 56.6% asymmetry. Nasal septum straight in 13.4%, right deviation in 35.3%, left deviation in 37.6%, sigmoid in 6%, reverse sigmoid in 6.3%, other patterns in 1.4% which is in concordance with our study. Gopal KS, et al.[29] 2016 used CBCT images to establish pattern of frontal sinus and nasal septum and reported its possible applications for personal identification. Frontal sinus symmetry was observed in 43.75% individuals and asymmetry in 48.75%. Bilateral aplasia in 5% and Unilateral aplasia was seen in 2.5%. Straight nasal septum was seen in 33.75%, right deviation in 30%, and left deviation in 22.5% individuals. Sigmoid was seen in 5%, reverse sigmoid in 8.75%. which was in concordance with our study. MP David & Saxena, et al.[30] 2010 reported use of frontal sinus and nasal septum for personal identification. Out of 50 cases 9 cases were found to have identical pattern with 82% probability of positive personal identification.

CONCLUSION

This study demonstrated that CBCT visualization of anatomical aspects and the pneumatisation of sphenoid sinuses can be used for personal identification. In our study, we observed that the frontal sinus and nasal septum patterns and sphenoid sinus had considerable individual variations and thus this study can be more reliable for personal identification. The usage of these parameters as seen in a full skull CBCT image can be used as one of the aids in personal identification. All three may vary person to person or even in monozygotic twins. Severely damaged bodies can be difficult to identify, and various factors can delay the identification. In violent traumatic contexts, teeth and frontal sinuses can be missing, which limits their contribution to identification. Sphenoid sinuses, on the other hand, are better protected from traumatic degradation as they are deeply positioned in the center of the cranial base. Their pneumatization, well documented as extremely variable in degrees and directions, could contribute to the radiologic identification of a dead person.
