Abstract

Stiff finger is a common condition found among the elder population due to various types of arthritis. In the younger age group it occur usually as a sequel of trauma. It is a difficult condition to treat and follow up. Patient cooperation and strict adherence to exercise routines in paramount for success of treatment of stiff finger. The ideal treatment includes release of the adhesions, active physiotherapy. However because of the covid 19 crisis, the usual treatments of the various disease have been compromised due to lack of travel, transport, need to maintain social distancing etc. We devised our own splint management for stiff finger and found it to be useful.

Keywords: Stiff finger; COVID-19; Corona pandemic.

INTRODUCTION

Stiff finger is a common condition found among the elder population due to various types of arthritis. In the younger age group it occur usually as a sequel of trauma. It is a difficult condition to treat and follow up. Patient cooperation and strict adherence to exercise routines in paramount for success of treatment of stiff finger. The ideal

treatment includes release of the adhesions, active physiotherapy. However because of the covid 19 crisis, the usual treatments of the various disease have been compromised due to lack of travel, transport, need to maintain social distancing etc. We devised our own splint management for stiff finger and found it to be useful.

METHODOLOGY

This study was conducted during the COVID-19 pandemic in a tertiary care center in the department of plastic surgery with departmental committee ethical approval. 48 year old gentleman with history of the hit of cricket ball on the tip of ring finger and had difficulty in movement of proximal interphalangeal joint (PIP) of ring finger with pain and edema of the finger 1 month back. Patient consulted the nearby indigenous treatment centre and treatment was done with massaging treatment.

high risk procedures like intubation, cauterization which are aerosol generating procedures have to be kept to a minimum to avoid exposure to the disease.

"Stiff finger," defined as a finger with decreased range of motion in single or multiple joints, is found after hand injury and is classified into flexion or extension deformities. The initial response to any injury is inflammation, with pain and edema. By 7 days leukocytes and mediators surround the injury resulting in proliferation phase, which lasts for approximately 3 weeks. Collagen gets deposited initially in a disorganized way, causing adhesions. The final stage of the response to injury is remodeling of disorganized collagen. At completion of this phase, complete healing with supple skin and soft tissue, and resolution of edema.

The initial treatment consists of a program aimed at softening and stretching scar tissue as well as maximizing passive range of motion (ROM).^{1,2,3} Exercises are often supplemented with splinting: dynamic, static-progressive, or serial static splints. All types of splints apply mechanical force to the joints at its end of motion to improve stretching of contracted tissues. Static and static-progressive splinting apply inelastic forces to the joint to position it with maximal stretch, but needs adjusted frequently. Dynamic splints apply a preset force across the joint using springs or elastics to position the joint at maximal stretch. Both types of splinting regimens have been demonstrated to be equally effective.³ In a series of 212 stiff joints, therapy alone successfully treated 87% of PIP joint and MCP joint contractures.⁴ The groups of Flowers and Glasgow⁵⁻⁷ demonstrated that passive ROM gains are a function of increasing the splint time and force applied. However, the optimal intensity and duration of therapy is ill defined. Excessive external force can cause damage from tearing of soft tissues and ligaments or articular subluxation. Time spent

splinting reach a practical maximum based on the limits of patient tolerance.^{5,7} Numerous researchers have investigated external splints for mobilizing a PIP joint flexion contracture.⁸⁻¹¹ These devices, which need to be fixed by surgery, apply skeletal traction across the PIP joint by gradual extension or distraction as the device gets adjusted. These devices stretch the deeper capsuloligamentous tissues and musculotendinous units but also stretch the soft tissue and fascia, like in Dupuytren contracture. Institutional results from these devices have shown promising improvements in PIP joint arc of motion, with a mean of 67 over long term follow-up.¹⁰

CONCLUSION

The splint allowed to provide continuous extensor pull on the PIPJ finger and stopped the progression of the contracture. Patient was asked to be on regular follow up till COVID crisis settles for definitive procedure.
